Statistical Methods for High Dimensional Biology

STAT/BIOF/GSAT 540

Lecture 7 – Beyond two groups

Sara Mostafavi

January 25 2016

Slides by Dr. Jennifer Bryan

outline

- Quick review of t test

- ANOVA: (one-way) analysis of variance

- Linear regression

Book recommendations

- Linear Models in R by Julian Faraway, Chapman & Hall/CRC Texts in Statistical Science, 2004

    (there is a related PDF book on web, seems to be an earlier but very mature draft of the official book)

- Applied Linear Statistical Models by Neter, Kutner, Nachtsheim, Wasserman. 4th ed, Irwin 1996 (there is a more recent version too)

- Vanables WN, Ripley BD. Modern Applied Statistics with S. 2002.

Review: two sample comparison

Question: are data from group 1 and group 2 generated by the same *model*?

Input: data from 2 groups, group memberships
Output(s): test statistics (optional), p-value for rejecting the null H_0

Steps:

1) Design a test statistics that quantifies the aspect of the *difference* you want to test – compute the *observed* value of the test statistics.

2) Use theory or "simulation" to come up with the distribution of test statistics under the null model.

3) Compute the probability of observing a test statistics as or more extreme as the observed on, under the null distribution for the test statistics.

Do you think the orange's and blue's are generated by different underlying distributions (models)?
Irs4 (insulin receptor substrate 4) was selected at random as a boring non differentially expressed gene; NrlKO ~= wt

Nrl (neural retina leucine zipper gene) is the gene that was knocked out in half the mice; obviously should be differentially expressed; NrlKO << wt

Linear models and test of group differences

- Two sample t test

- ANOVA: analysis of variance

- Linear regression

```
> t.test(gExp ~ gType, miniDat,
+         subset = gene == "Irs4", var.equal = TRUE)
```

two sample t test

```
> summary(aov(gExp ~ gType, miniDat,
+             subset = gene == "Irs4"))
```

(one-way) analysis of variance
"ANOVA"

```
> summary(lm(gExp ~ gType, miniDat,
+            subset = gene == "Irs4"))
```

linear model
linear regression

```
> t.test(gExp ~ gType, miniDat,
+         subset = gene == "Irs4", var.equal = TRUE)

        Two Sample t-test

data:  gExp by gType
t = 0.5286, df = 37, p-value = 0.6002
<snip, snip>
sample estimates:
   mean in group wt mean in group NrlKO
          7.765750             7.739684

> summary(aov(gExp ~ gType, miniDat,
+             subset = gene == "Irs4"))
            Df Sum Sq Mean Sq F value Pr(>F)
gType        1 0.0066 0.00662   0.279    0.6
Residuals   37 0.8764 0.02369
```

Irs4

$\overline{Z} = 7.74$

$\overline{Y} = 7.77$

7.739684 − 7.765750 = −0.026066

−0.5286494 ^ 2 = 0.2794702

```
> summary(lm(gExp ~ gType, miniDat,
+            subset = gene == "Irs4"))
<snip, snip>
Coefficients:
             Estimate Std. Error t value Pr(>|t|)
(Intercept)  7.76575    0.03441 225.650   <2e-16 ***
gTypeNrlKO  -0.02607    0.04931  -0.529      0.6
<snip, snip>
F-statistic: 0.2795 on 1 and 37 DF,  p-value: 0.6002
```

These are not coincidences!

The two sample t test is a special case of "analysis of variance" or "ANOVA", where the only difference is two groups vs. potentially more than two groups.

"Analysis of variance" or "ANOVA" is a special case of a linear model or linear regression, where the only real difference is categorical covariates only vs. potentially including quantitative covariates. There are also different in conventions around reporting results.

Given that you may want to model complex data, I recommend:

- get comfortable with linear models and view "group comparisons" as a special case

To demonstrate the connection between these approaches, we will change the problem formulation:

Previously, we wrote *Y ~ F* (Y is modeled by distribution F)

Now, we will think about modeling the rv Y using its mean and variability around it's mean:

$$Y = \mu + \varepsilon \quad \text{where } \varepsilon \sim F, E(\varepsilon) = 0$$

Change of notation:

In our running example, I used Y and Z to denote the random variables corresponding to some quantity we might observe for subjects in two groups.

One group, wild type … Y

Other group, NrlKO … Z

Now:

We'll follow statistical convention for formulating regression.

Y: a variable we observe (response)

X: predictor or explanatory variables (distinction between wild type and knockout)

# Let's map this notation/formulation to our working example

Group 1 (WT)

$$Y_1 = \mu_1 + \varepsilon_1 \quad \text{where } \varepsilon_1 \sim F, E(\varepsilon_1) = 0$$

Group 2 (NrlKO)

$$Y_2 = \mu_2 + \varepsilon_2 \quad \text{where } \varepsilon_2 \sim F, E(\varepsilon_2) = 0$$

* Note that we have a different expected value μ_j for each group

* With this formulation, we can actually have many groups, not just 2!

* Note that we are assuming the same noise distribution for the two groups (can be relaxed if we think it should be …)

Our observed data will be observations of the Y_j, where we assume independence across observations. Individual observations or experimental units are denoted by i:

$$Y_{ij} = \mu_j + \varepsilon_{ij}, \text{ where } \varepsilon_{ij} \sim F, E(\varepsilon_{ij}) = 0$$

(b) Analysis of Variance Model

$$Y_{ij} = \mu_j + \varepsilon_{ij}, \text{ where } \varepsilon_{ij} \sim F, E(\varepsilon_{ij}) = 0$$

**(b) Analysis of Variance Model**

We will, of course, want to know if all the μ_j are the same or not and, if not, which ones are different.

That will be judged based on whether observed differences in sample averages are large based on the apparent background variability.

$$Y_{ij} = \mu_j + \varepsilon_{ij}, \text{ where } \varepsilon_{ij} \sim F, E(\varepsilon_{ij}) = 0$$

$$
\begin{bmatrix}
Y_{11} \\
\vdots \\
Y_{n_1 1} \\
Y_{12} \\
\vdots \\
Y_{n_2 2}
\end{bmatrix}
=
\begin{bmatrix}
\mu_1 \\
\vdots \\
\mu_1 \\
\mu_2 \\
\vdots \\
\mu_2
\end{bmatrix}
+
\begin{bmatrix}
\varepsilon_{11} \\
\vdots \\
\varepsilon_{n_1 1} \\
\varepsilon_{12} \\
\vdots \\
\varepsilon_{n_2 2}
\end{bmatrix}
$$
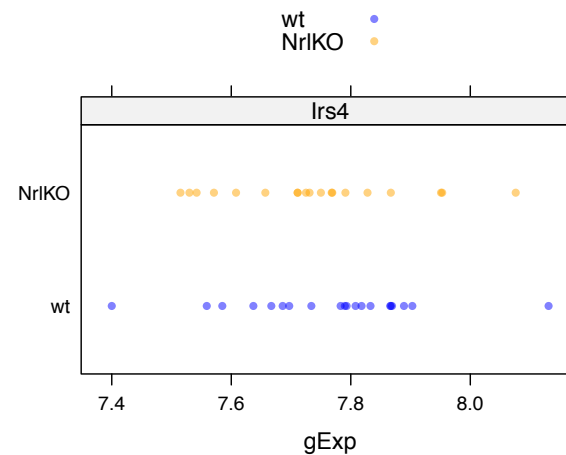

I constructed this vector "by hand" -- whenever the Y_{ij} is from group 1, I put in μ_1, and when Y_{ij} is from group 2, I put in μ_2.

For mathematical and computational reasons, a matrix formulation is advantageous.

Now let's write the exact same time in a slightly different way

$$Y_{ij} = \mu_j + \varepsilon_{ij}, \text{ where } \varepsilon_{ij} \sim F, E(\varepsilon_{ij}) = 0$$

$$\begin{bmatrix} Y_{11} \\ \vdots \\ Y_{n_1 1} \\ Y_{12} \\ \vdots \\ Y_{n_2 2} \end{bmatrix} = \begin{bmatrix} 1 & 0 \\ \vdots & \vdots \\ 1 & 0 \\ 0 & 1 \\ \vdots & \vdots \\ 0 & 1 \end{bmatrix} \begin{bmatrix} \mu_1 \\ \mu_2 \end{bmatrix} + \begin{bmatrix} \varepsilon_{11} \\ \vdots \\ \varepsilon_{n_1 1} \\ \varepsilon_{12} \\ \vdots \\ \varepsilon_{n_2 2} \end{bmatrix} = \begin{bmatrix} \mu_1 \\ \vdots \\ \mu_1 \\ \mu_2 \\ \vdots \\ \mu_2 \end{bmatrix} + \begin{bmatrix} \varepsilon_{11} \\ \vdots \\ \varepsilon_{n_1 1} \\ \varepsilon_{12} \\ \vdots \\ \varepsilon_{n_2 2} \end{bmatrix}$$

Example of a "design matrix"; often denoted by X in the statistical world.

the column vector of the responses
one element per experimental unit

a column vector
of the errors

$$Y = X\alpha + \varepsilon$$

a (design) matrix that represents covariate
info, one row per experimental unit

a column vector of the parameters in the
linear model

Generic linear model, using
conventional matrix formulation

$$Y = X\alpha + \varepsilon$$

The exact form of the design matrix X and the parameter alpha are not uniquely defined. The user has some control. The two objects are tightly related to each other. This will become much more clear in examples.
$$\begin{bmatrix} Y_{11} \\ \vdots \\ Y_{n_1 1} \\ Y_{12} \\ \vdots \\ Y_{n_2 2} \end{bmatrix} = \begin{bmatrix} 1 & 0 \\ \vdots & \vdots \\ 1 & 0 \\ 0 & 1 \\ \vdots & \vdots \\ 0 & 1 \end{bmatrix} \begin{bmatrix} \mu_1 \\ \mu_2 \end{bmatrix} + \begin{bmatrix} \varepsilon_{11} \\ \vdots \\ \varepsilon_{n_1 1} \\ \varepsilon_{12} \\ \vdots \\ \varepsilon_{n_2 2} \end{bmatrix}$$
$$Y = X\alpha + \varepsilon$$

Here's an example of a design matrix X and parameter vector alpha that work together. But there are others!

ANOVA-style
"cell means" parametrization

$$Y_{ij} = \mu_j + \varepsilon_{ij}$$

ANOVA-style
"reference + treatment effects"
parametrization

$$Y_{ij} = \theta + \tau_j + \varepsilon_{ij}, \text{ where } \tau_1 = 0 \text{ by convention}$$

The same model is being used, under the hood, but it is represented -- "parametrized" -- differently. Different parametrizations are useful for different things.

ANOVA-style
"cell means" parametrization

$$Y_{ij} = \mu_j + \varepsilon_{ij}$$

ANOVA-style
"reference + treatment effects"
parametrization

$$Y_{ij} = \theta + \tau_j + \varepsilon_{ij}, \text{ where } \tau_1 = 0 \text{ by convention}$$
Here's how we would represent the state of "all groups have same mean", in either parametrization:

$$\mu_1 = \mu_2 = \mu_3 \quad \Leftrightarrow \quad \tau_2 = \tau_3 = 0$$

ANOVA-style, "cell means"

$$Y_{ij} = \mu_j + \varepsilon_{ij}$$

ANOVA-style, "ref + tx effects"

$$Y_{ij} = \theta + \tau_j + \varepsilon_{ij}, \ (\tau_1 = 0)$$

$$Y = X\alpha + \varepsilon$$

$$
\begin{bmatrix} y_{11} \\ y_{21} \\ \vdots \\ \\ y_{n_3 3} \end{bmatrix}
=
\begin{bmatrix}
1 & 0 & 0 \\
\vdots & \vdots & \vdots \\
1 & 0 & 0 \\
0 & 1 & 0 \\
\vdots & \vdots & \vdots \\
0 & 1 & 0 \\
0 & 0 & 1 \\
\vdots & \vdots & \vdots \\
0 & 0 & 1
\end{bmatrix}
\begin{bmatrix} \mu_1 \\ \mu_2 \\ \mu_3 \end{bmatrix}
+
\begin{bmatrix} \varepsilon_{11} \\ \varepsilon_{21} \\ \vdots \\ \\ \varepsilon_{n_3 3} \end{bmatrix}
\qquad
\begin{bmatrix} y_{11} \\ y_{21} \\ \vdots \\ \\ y_{n_3 3} \end{bmatrix}
=
\begin{bmatrix}
1 & 0 & 0 \\
\vdots & \vdots & \vdots \\
1 & 0 & 0 \\
1 & 1 & 0 \\
\vdots & \vdots & \vdots \\
1 & 1 & 0 \\
1 & 0 & 1 \\
\vdots & \vdots & \vdots \\
1 & 0 & 1
\end{bmatrix}
\begin{bmatrix} \theta \\ \tau_2 \\ \tau_3 \end{bmatrix}
+
\begin{bmatrix} \varepsilon_{11} \\ \varepsilon_{21} \\ \vdots \\ \\ \varepsilon_{n_3 3} \end{bmatrix}
$$

The design matrix specifies how the observed
data relates to the regression parameters.

Note we can obtain one set of parameters from the others!

$$\mu_1 \qquad \mu_2 \qquad\qquad \mu_3$$

ANOVA-style, "cell means"

$$Y_{ij} = \mu_j + \varepsilon_{ij}$$

|					
μ_1	$=$	θ	θ	$=$	μ_1
μ_2	$=$	$\theta + \tau_2$	τ_2	$=$	$\mu_2 - \mu_1$
μ_3	$=$	$\theta + \tau_3$	τ_3	$=$	$\mu_3 - \mu_1$

$$Y_{ij} = \theta + \tau_j + \varepsilon_{ij}, (\tau_1 = 0)$$

ANOVA-style, "ref + tx effects"

We can do this neatly with matrix multiplication!
The matrices C below are sometimes called "contrast matrices".

$$\mu_1 \quad \mu_2 \qquad \qquad \mu_3$$

ANOVA-style, "cell means"

$$Y_{ij} = \mu_j + \varepsilon_{ij}$$

τ_2

τ_3

θ

$$\begin{bmatrix} 1 & 0 & 0 \\ 1 & 1 & 0 \\ 1 & 0 & 1 \end{bmatrix} \begin{bmatrix} \theta \\ \tau_2 \\ \tau_3 \end{bmatrix} = \begin{bmatrix} \mu_1 \\ \mu_2 \\ \mu_3 \end{bmatrix} \qquad \begin{bmatrix} 1 & 0 & 0 \\ -1 & 1 & 0 \\ -1 & 0 & 1 \end{bmatrix} \begin{bmatrix} \mu_1 \\ \mu_2 \\ \mu_3 \end{bmatrix} = \begin{bmatrix} \theta \\ \tau_2 \\ \tau_3 \end{bmatrix}$$

$$C^T \begin{bmatrix} \theta \\ \tau_2 \\ \tau_3 \end{bmatrix} = \mu \qquad \qquad C^T \mu = \begin{bmatrix} \theta \\ \tau_2 \\ \tau_3 \end{bmatrix}$$

$$Y_{ij} = \theta + \tau_j + \varepsilon_{ij}, \ (\tau_1 = 0)$$

ANOVA-style, "ref + tx effects"

How works in practice using lm() in R

$$Y = X\alpha + \varepsilon$$

$\downarrow$

```
lm(y ~ x, data = jDat)
```

formula
y numeric
x factor

optional data.frame in which x
and y are to be found (I
recommend this style)

R formulas are expressed in 'Wilkinson-Rogers' notation. See
Venables and Ripley 3.7 and 6.2 for an introduction. And/or
read Ch. 11 of "An Introduction to R".

$$Y = X\alpha + \varepsilon$$ `lm(y ~ x, data = jDat)`

In most contexts, you can -- and should! -- just let R create the design matrix X for you.

How factors are "dummied out" is controlled by how you specify the model and the current "contrasts" setting in effect.

The path of least resistance will be "reference + treatment effects" (called "contr.treatment"; see ?options and ?contrasts and ?contr.treatment to learn more.)

If you really want to -- or must -- do it yourself, see `model.matrix()`. Also nice just for viewing and getting acquainted with the contrasts associated with a factor.

Vocabulary: **contrasts**

The word **contrasts** is used in stats for some distinct but closely related things. You've already seen that just now:

1. the "contrasts for a factor", i.e. specific choice of "dummying" out a factor in regression
2. a "contrast matrix" to map one set of parameters to another, to form linear combinations of parameters

the "contrasts for a factor", i.e. specific choice of "dummying" out a factor in regression

This occurs on the "front end" of modelling, i.e. when specifying the model parametrization or, equivalently, when specifying the contrasts for factor covariates or, equivalently, when creating the design matrix.

ANOVA-style, "cell means"

$$Y_{ij} = \mu_j + \varepsilon_{ij}$$

ANOVA-style, "ref + tx effects"

$$Y_{ij} = \theta + \tau_j + \varepsilon_{ij}, (\tau_1 = 0)$$

$$Y = X\alpha + \varepsilon$$

$$
\begin{bmatrix} y_{11} \\ y_{21} \\ \vdots \\ y_{n_3 3} \end{bmatrix} =
\begin{bmatrix}
1 & 0 & 0 \\
\vdots & \vdots & \vdots \\
1 & 0 & 0 \\
0 & 1 & 0 \\
\vdots & \vdots & \vdots \\
0 & 1 & 0 \\
0 & 0 & 1 \\
\vdots & \vdots & \vdots \\
0 & 0 & 1
\end{bmatrix}
\begin{bmatrix} \mu_1 \\ \mu_2 \\ \mu_3 \end{bmatrix} +
\begin{bmatrix} \varepsilon_{11} \\ \varepsilon_{21} \\ \vdots \\ \varepsilon_{n_3 3} \end{bmatrix}
$$

$$
\begin{bmatrix} y_{11} \\ y_{21} \\ \vdots \\ y_{n_3 3} \end{bmatrix} =
\begin{bmatrix}
1 & 0 & 0 \\
\vdots & \vdots & \vdots \\
1 & 0 & 0 \\
1 & 1 & 0 \\
\vdots & \vdots & \vdots \\
1 & 1 & 0 \\
1 & 0 & 1 \\
\vdots & \vdots & \vdots \\
1 & 0 & 1
\end{bmatrix}
\begin{bmatrix} \theta \\ \tau_2 \\ \tau_3 \end{bmatrix} +
\begin{bmatrix} \varepsilon_{11} \\ \varepsilon_{21} \\ \vdots \\ \varepsilon_{n_3 3} \end{bmatrix}
$$

```
lm(y ~ 0 + x, data = jDat)
lm(y ~ -1 + x, data = jDat)
```

```
lm(y ~ x, data = jDat)
```

Controlling parametrization (or the factor contrasts) via the model formula.

a "contrast matrix" to map one set of parameters to another, to form linear combinations of parameters

This occurs on the "back end" of modelling. Example, if a parameter you are interested in is not one of those being directly estimated, but it can be formed as a linear combination regression parameters, i.e. via a "contrast matrix".
Typical use: to form a difference of group means.

$$Y_{ij} = \mu_j + \varepsilon_{ij}$$

Let's imagine you want to fit the model with a cell means parametrization.

But you also want to look at the differences between the cell means.

$\mu_1 \quad \mu_2 \qquad\qquad \mu_3$

You could do that by multiplying the vector of parameter (or their estimates) by a "contrast matrix".

$$\begin{bmatrix} -1 & 1 & 0 \\ -1 & 0 & 1 \\ 0 & -1 & 1 \end{bmatrix} \begin{bmatrix} \mu_1 \\ \mu_2 \\ \mu_3 \end{bmatrix} = C^T \mu = \begin{bmatrix} \mu_2 - \mu_1 \\ \mu_3 - \mu_1 \\ \mu_3 - \mu_2 \end{bmatrix}$$

Why am I burdening you with this? Doesn't R and the lm() function, in particular, default to something reasonable?

Yes it does. But ...

1. Once you get beyond two group comparisons, you need to know a bit about how factors are utilized in linear models and what the resulting parameter estimates mean. One day you may even want to exert control on this.

Why am I burdening you with this? cont'd

2. A popular R package for performing linear modelling for thousands of, e.g., genes at once, while borrowing strength across the genes, is called limma (see later lectures).
And, unlike lm(), limma does NOT make the design matrix for you. limma does not use the same formula interface as lm().

This is sad.

Why would you still want to use limma? Because it implements moderation of the t-statistics for regression parameters, using an empirical Bayes approach.

Why was limma written this way? For historical reasons, due to idiosyncrasies of two-channel microarrays.

Do we think the expression levels at different developmental stages are generated by different underlying distributions? Or a common one?

$$Y = X\alpha + \varepsilon$$

$$\alpha = (\theta, \tau_{P2}, \tau_{P6}, \tau_{P10}, \tau_{4\_weeks})$$

in the context of this model we generally test null hypotheses of two types:

$H_0 : \tau_j = 0$

vs

$H_0 : \tau_j \neq 0$

for each j individually

$H_0 : \tau_j = 0$

vs

$H_0 : \tau_j \neq 0$

for all j at the same time

$$Y = X\alpha + \varepsilon$$

$$\alpha = (\theta, \tau_{P2}, \tau_{P6}, \tau_{P10}, \tau_{4\_weeks})$$

$H_0 : \tau_j = 0$

vs

$H_0 : \tau_j \neq 0$

for each j individually

$H_0 : \tau_j = 0$

vs

$H_0 : \tau_j \neq 0$

for all j at the same time

<snip, snip>
Residual standard error: 0.2702 on 34 degrees of freedom
F-statistic:  4804 on 5 and 34 DF,  p-value: < 2.2e-16
```

These p-values are for these tests:

$$H_0 : \mu_j = 0$$

Probably not what you're really interested in! Boo.

```
               theHitAvgs
E16              5.540857
P2               5.844875
P6               5.784250
P10              6.375125
4_weeks          9.173375
```

Different parametrizations are useful for different things, but in some aspects, such as residual error, they are equivalent.

```
hitFit <- lm(gExp ~ devStage, miniDat, gene == "theHit")
```

Residual standard error: 0.2702 on 34 degrees of freedom
Multiple R-squared: 0.9663,   Adjusted R-squared: 0.9623
F-statistic: 243.4 on 4 and 34 DF, p-value: < 2.2e-16

```
hitFitCellMeans <- lm(gExp ~ 0 + devStage, miniDat, gene == "theHit")
```

Residual standard error: 0.2702 on 34 degrees of freedom
Multiple R-squared: 0.9986,   Adjusted R-squared: 0.9984
F-statistic: 4804 on 5 and 34 DF, p-value: < 2.2e-16

?? Note: The artificiality of the "group means" model is highlighted here, in that overall significance arises from comparison to no model at all, i.e. $E(Y_j) = 0$.
